# Problem 1: Vectors in R

#### **Vector Definition**

Although there exists a function called vector() in R, vectors are always defined in R using the function c() which stands for "concatenation".

#### Vector Assignment

Let us assume we want to assign the following vector a

$$a = \begin{bmatrix} 10 \\ 7 \\ 43 \end{bmatrix}$$

to the variable named a in R, then this can be done with the following statement

 $a \leftarrow c(10,7,43)$ 

# Access of single Vector Element

A single vector element can be accessed using the variable name followed by the element index in brackets. Hence, if we want to know the first element of vector **a**, we have to write

a[1]

## [1] 10

#### Computations with Vector Elements

Vector elements can be used in arithmetic operations such as summation, subtraction and multiplication as shown below

a[1] + a[3]

## [1] 53

a[2] \* a[3]

## [1] 301

a[3] - a[1]

## [1] 33

The function sum() can be used to compute the sum of all vector elements. The function mean() computes the mean of all vector elements.

sum(a)

## [1] 60

mean(a)

## [1] 20

### **Vector Computations**

Arithmetic operations can also be performed not only on elements of vectors but also on complete vectors. Hence, we can add the vector **a** to itself or we can multiply it by a factor of 3.5 which is shown in the following code-chunk

a + a

## [1] 20 14 86

3.5 \* a

**##** [1] 35.0 24.5 150.5

# ${\bf More\ Computations\ on\ Vectors}$

Given are the following two vectors v and w.

$$v = \begin{bmatrix} 3 \\ -5 \\ 1 \\ 9 \end{bmatrix}$$

$$w = \begin{bmatrix} 1\\9\\-12\\27 \end{bmatrix}$$

# Compute

- the sum v + w,
- the difference v-w and
- the dot product  $v \cdot w$ .

#### Solution

```
v \leftarrow c(3, -5, 1, 9)

w \leftarrow c(1, 9, -12, 27)
```

Now we do the computations.

The sum v + w is

v+w

```
## [1] 4 4 -11 36
```

The difference v-w is

v-w

```
## [1] 2 -14 13 -18
```

and the dot-product is

```
crossprod(v,w)
```

```
## [,1]
## [1,] 189
```

or

```
v %*% w
```

```
## [,1]
## [1,] 189
```

**Please note**: Although the R-function is called crossprod() what is computed is the dot product between the two vectors. The function name crossprod() is used because in Statistics the product  $(X^TX)$  of a transposed matrix  $(X^T)$  and itself (X) is called a matrix crossproduct. This has nothing to do with the crossproduct  $v \times w$  between two vectors v and w.

# Problem 2: Matrices in R

Matrices in R are defined using the function matrix(). The function matrix() takes as first arguments all the elements of the matrix as a vector and as further arguments the number of rows and the number of columns. The following statement generates a matrix with 4 rows and 3 columns containing all integer numbers from 1 to 12.

```
mat_by_col <- matrix(1:12, nrow = 4, ncol = 3)
mat_by_col</pre>
```

```
##
         [,1] [,2] [,3]
## [1,]
                  5
             1
            2
                   6
   [2,]
                       10
            3
## [3,]
                   7
                       11
   [4,]
             4
                       12
```

As can be seen, the matrix elements are ordered by columns. Often, we want to define a matrix where elements are filled by rows. This can by done using the option byrow=TRUE

```
mat_by_row <- matrix(1:12, nrow = 4, ncol = 3, byrow = TRUE)
mat_by_row</pre>
```

```
##
         [,1] [,2] [,3]
## [1,]
                   2
             1
## [2,]
            4
                   5
                        6
## [3,]
            7
                        9
                  8
                       12
## [4,]
           10
                 11
```

#### **Access of Matrix Elements**

Matrix elements can be accessed similarly to what was shown for vectors. But to access a single element, we need two indices, one for rows and one for columns. Hence the matrix element in the second row and third column can be accessed by

```
mat_by_row[2,3]
```

## [1] 6

#### **Arithmetic Computations with Matrices**

Arithmetic computations with matrices can be done with the well-known operators as long as the matrices are compatible. For summation and subtraction matrices must have the same number of rows and columns. For matrix-multiplication, the number of columns of the first matrix must be equal to the number of rows of the second matrix.

In R the arithmetic operators +, - and \* all perform element-wise operations. The matrix multiplication can either be done using the operator %\*% or the function crossprod(). It has to be noted that the statement

```
crossprod(A, B)
```

computes the matrix-product  $A^T \cdot B$  where  $A^T$  stands for the transpose of matrix A. Hence the matrix product  $A \cdot B$  would have to be computed as

```
crossprod(t(A), B)
```

# More Examples

Given the matrices X and Y

```
X <- matrix(1:15, nrow = 5, ncol = 3)</pre>
Y \leftarrow matrix(16:30, nrow = 5, ncol = 3)
```

# Compute

- *X* + *Y*
- Y − X
- ullet multiplication of elements between X and Y
- matrix-product  $X^T \cdot Y$  matrix-product  $X^T \cdot X$
- $\bullet \ \ \text{matrix-product} \ Y^T \cdot Y$

## [2,] 730 930 1130 ## [3,] 1180 1505 1830

# Solution
